Abstract

Simplifying complex species interactions can facilitate prediction of changes in ecosystem function and structure under climate change. This is particularly important for highly migratory pelagic predators, which exploit diverse prey fields as they respond to dynamic environments. We reconstructed the historical resource use of albacore tuna (*Thunnus alalunga*) globally and confirmed highly biodiverse diets with 308 prey identified to species, and 279 at lower taxonomic resolution. We quantitatively synthesised prey diversity into 7 functional trait guilds using four traits that influence predator-prey encounter rates – prey habitat association, seasonal and diel vertical migration behaviour – using hierarchical divisive clustering algorithms. We further explore variability in historical composition of albacore diets across geographies based on species identity, individual trait information, and functional trait guilds using a multi-matrix modelling framework. Species-based diet composition was highly variable across geographies and years sampled. Trait-based models of albacore diets highlight the historical importance of near-surface epipelagic prey resources from coastal to oceanic habitats, and seasonally-migrating continental shelf prey, compared to less frequent pulses of deeper water and demersal taxa. Our

results indicate that trait information and trait guilds serve as useful classification frameworks for identifying functionally redundant food web linkages involving biodiverse prey, and will prove useful in tracking predators' foraging responses to changing ecological states.

Table of Contents

1. Introduction

Pelagic ecosystems are among the last frontiers on Earth, politically and ecologically. Yet stressors such as climate change and intensive fishing efforts (Casini et al., 2009; Poloczanska et al., 2016) are altering the distributions and composition of pelagic communities (Hazen et al., 2013; Cheung et al., 2015; Morley et al., 2018), causing widespread species extirpations and undesirable ecosystem states (Polovina et al., 2011; Molinos et al., 2016). Altered pelagic ecosystem states can lead to changes in fisheries production and uncertain economic futures (Cheung et al., 2010; Blenckner et al., 2015; Free et al., 2019). Within pelagic systems, highly migratory predators such as tunas and billfishes contribute to valuable and extensive

77 international fisheries (Sala et al., 2018). These species evolved to migrate across ocean basin
78 scales in order to exploit seasonal food resources for growth and warmer waters for reproduction
79 (Mariani et al., 2016). However, anomalies and long-term changes in climate are producing
80 mismatches among predator migration and the productivity of forage resources, with
81 implications for fisheries productivity (Thackeray et al., 2010; Scheffers et al., 2016).
82 Accounting for trophic interactions is often the missing link to forecasting species
83 redistributions under climate change (Lan et al., 2021; Green et al., 2022), especially for highly
84 migratory marine species (Muhling et al., 2019). Marine species redistributions are typically
85 predicted on the basis of habitat use and changing physical oceanographic properties (Morley et
86 al., 2018). Despite empirical relationships between the biomass of prey species and their
87 prevalence in predator diets, efforts to model predator distributions in relation to the distribution
88 of key prey are often plagued by numerous issues including the accuracy of prey distribution
89 information (Muhling et al. 2019), the number and functional redundancy of interacting species
90 (Link, 2007; Carroll et al., 2019). These hurdles may be overcome by modelling functional
91 ecological relationships using synthetic parameters, or traits (Zakharova et al., 2019; Green et al.
92 2022).

Trait-based approaches to modelling predator-prey interactions aim to simplify taxonomically complex interactions among hundreds of species to synthetic and non-taxonomic predictors for those relationships, positioning scientists to predict ecological outcomes in new contexts (McGill et al., 2006; Kiørboe et al., 2018; Green et al., 2022). For example, the strength of predator-prey interactions can be modelled as a function of single or multiple individual prey trait variables influencing the predation process (Arrizabalaga-Escudero et al., 2019; Green et al., 2022). Additionally functional groupings of prey into 'guilds' are a common ecological practice of dimension or variable reduction (Pomerleau et al., 2015; Parravicini et al., 2020), based on shared traits describing similar roles for those species in ecosystem processes (Gitay & Noble, 1997) in order to model complex species distribution and interactions.

Trait-based approaches may be particularly useful for tunas – that have taxonomically broad diets (Duffy et al., 2017; Pethybridge et al., 2018) and there is little evidence for the influence of predator size on prey size selection (Romanov et al., 2020). While these foraging properties make them salient indicator species to track changing prey communities and predator-prey interactions under climate change, they also make them excellent candidates for trait-based modelling to synthesise complex interactions with numerous prey species and investigate

evidence for selection for certain types of forage (Glaser, 2010; Valls et al., 2022). Previous diet analyses related shifts and niche partitioning in the diets of yellowfin, bluefin, bigeye and albacore tunas across predator species, latitude, predator life stage, environmental drivers (Allain et al., 2012; Young et al., 2015; Duffy et al., 2017; Pethybridge et al., 2018; Portner et al., 2022; Valls et al., 2022; Nickels et al., 2023), and shifts in albacore distribution have been linked to prey availability (Pearcy, 1973). Many of these studies hypothesise about the role of traits in driving observed patterns and shifts. However, the extent to which trait information could explicitly be used to explain tuna foraging ecology across space and time and predict their resource use under changing environmental states remains poorly understood.

Using albacore (*Thunnus alalunga*) as a case study, we seek to move beyond descriptive diet analyses to identifying non-taxonomic predictors for trophic relationships in highly-migratory pelagic predators and commercially valuable species. Our synthesis aggregates historical data on albacore diets from published and grey literature dating from 1880–2020 globally. Our aims are threefold, to: (1) reconstruct historical resource use for albacore across geographies from published aggregate mean diet composition data, (2) use functional traits to distil diverse predator-prey interactions into key trait-based guilds, and (3) explore species-based and trait-based variability in the historical composition of albacore diets across the geographies sampled.

2. Methods

2.1 Historical diet data collation

Our synthesis required quantitative data on adult or juvenile albacore diet composition obtained from stomach content analyses that identified consumed prey to species-level. To obtain these data, we compiled published and grey literature, research theses, and historical reports for albacore diets by searching bibliographic databases (Table S1) queried from 1900 until 2020 using diet analysis search terms and synonymous scientific names for albacore (*Thunnus alalunga*; Supporting Information, Table S1). We also investigated diet reports cited within articles, which expanded our range to include several reports from the 1880s. Studies typically reported a mix of data types (i.e., frequency of occurrence and other metrics).

We obtained diet data from 26 studies that were suitable for meta-analysis (Supporting Information, Table S2); this included 69 independent, aggregate (i.e. by geographic region, year, or season sampled) observations of adult and juvenile albacore diet composition, from 1880–2015 (Supplementary Data, Table S3). We digitised and transcribed data reported typically for a specific geographic location (Figure 1a), year, and season sampled. However, several reports presented information that was further aggregated for multi-year sampling programs (Table S3) and for analyses in these cases, we use the last year of sampling completed. Albacore were typically collected either via scientific sampling programs (i.e., National Oceanic and Atmospheric Administration [NOAA], Centre National de la Recherche Scientifique [CNRS]),

or in collaboration with commercial fishing operations (Bello, 1999; Joubin & Rouie, 1918; Glaser et al., 2015; Romanov et al., 2020), and using surface troll, pole-and-line, longlining at specified depths, or purse seining gear (Table S3).

2.2 Prey life stage estimation

Albacore consume post-larval and juvenile prey as well as adult life stages. Given that traits could vary between life stages for many species, we aimed to match traits to the life stage most commonly consumed by albacore predators for each prey species. Of the 308 prey recorded to species, 72 (or 23%) had associated life stage information reported within their corresponding diet study, with 42 reported as post-larvae, young-of-year, or juveniles, and 37 species consumed as adults (Supplementary Information, Figure S1). Albacore rarely consumed larvae (i.e., 11 species in total). Of these 72 species, 13 were reported at multiple life stages in albacore diets, however, one life stage was typically dominant across diet studies (i.e., with an order of magnitude greater frequency of occurrence than any other life stage). For example, of 11 species with reported consumption of the larval life stage, 6 species were typically consumed as juveniles (i.e. across multiple studies) and thus were assigned as juveniles for the purpose of this meta-analysis (Supplementary Data, Table S4; Supplementary Information, Figure S1).

When life stage information was not provided, it was necessary to estimate prey life stage from available information on the size and age class of either the predator or prey in a given study (Figure S1; Table S4). For an additional 15 species (nearly 5% of species), prey length

information was reported but not life stage. Reported total lengths ranged from 1.5–24.5 cm, and these prey species' life stages were inferred relative to their known length at maturity (Figure S1; Table S4). The remaining 221 species (72% of the species) were identified in albacore diets without metainformation and assumed to be either juveniles or adults. Trait information was often similar between juvenile and adult life stages (Gleiber et al., 2022). Thus for 127 of these taxa (41% of the species), no further estimation of prey life stage was needed.

Trait information differed by life stage for 94 prey species (31% of the species) remaining; for example, these could include a benthic adult with a pelagic juvenile life stage (Figure S1). Here, the most plausible life stage consumed was then assessed on a case-by-case basis (Table S4). As albacore are epipelagic predators, the pelagic stage of these prey was most likely consumed, and albacore are more likely to consume smaller juvenile prey, for example epipelagic juvenile hake (less than 10 cm and up to 20 cm length) than benthopelagic adult hake (~40–90 cm) (Bailey et al., 1982). We corroborated these decisions based on calculated maxillary length (or 'gape limit') for albacore sampled to determine whether adult prey could feasibly have been consumed from a published relationship between length and gape for closely-related yellowfin tuna (Ménard et al., 2006). Depending on the data reported, we used either a measured maximum albacore fork length (FL) (51 species [16%]), or an estimated maximum FL for the population of albacore sampled for each study that did not measure or report albacore lengths sampled (43 species [14%]), as inputs to the equation (Figure S1) (Ménard et al., 2006). Where albacore lengths were not reported, we matched gear-specific length data (range and mean FL) from relevant regional fisheries management organisations (ICCAT, 2020; ISC, 2006) to albacore diet studies by year. There was no significant difference between the variances of

mean, minimum and maximum FL for studies where these parameters were measured or where these parameters were estimated in this study (Figure S2). This process of estimating albacore length information resulted in estimated gape limits of 6.4–11.5 cm across studies and locations sampled, and affected only 14% of decisions on prey life stage and selection of appropriate trait information (Figure S1). Further detail in estimating the mean and range in albacore lengths for a given study are further described in Supplementary Information (Supplementary Information, Appendix B). Overall, our synthesis uses the following prey life stages consumed by albacore: 5 larval life stages, 210 juveniles, and 93 adult prey (Supplementary Data, Table S5).

2.3 Prey trait information

For each prey species and life stage (i.e., larva, juvenile, adult), we collected information for four habitat use traits known to affect the likelihood of pelagic predators encountering and consuming prey (Green et al., 2019). These were: (i) vertical and (ii) horizontal habitat association, (iii) presence of diel vertical migration, and (iv) presence of seasonal migration and seasonal aggregation behaviour (Table 1; Table S5). These trait data were compiled for a broader database of traits that inform predator-prey interactions for albacore (Gleiber et al., 2022). We further describe how prey species' trait values were used in Supporting Information, Appendix C.

2.4 Trait-based analyses

All data manipulation, statistical analysis and graphical illustrations were performed in *R* (version 4.2.1) (R Core Team, 2022).

Taxonomic and trait diversity in albacore diets

Species accumulation was calculated and plotted using *BiodiversityR* (version 2-14.1; Kindt & Coe, 2005) in relation to ocean basins where sampling locations occurred and the final year sampled (n = 69 observations) by each study (n = 26). Prey species' phylogenetic information were extracted from the Open Tree of Life Data using the package *rotl* (version 3.0.12) (Michonneau et al., 2016) and parsed to a phylogenetic tree using *ape* (version 5.6-2) (Paradis & Schliep, 2019) and *stringr* (version 1.4.0) (Wickham, 2021) with integrated species-specific trait information displayed using *ggtree* (v3.3.1.900) (Yu et al., 2017) to visualise relationships between taxonomic and trait diversity in the data.

Albacore prey trait guilds

229 For the 292 prey species with complete trait information, key prey trait guilds were identified
230 using a divisive hierarchical clustering algorithm (Anderberg, 1973; Legendre & Legendre,
231 1998) on a Gower dissimilarity matrix (Gower, 1971) to identify relational structure among
232 albacore prey in relation to ecological trait data for the four habitat use variables: two binomial
233 variables (seasonal and diel vertical migration) and two multi-level categorical variables (vertical
234 and horizontal habitat use) (Table 1; Supplementary Data, Table S4) using the *diana* algorithm in
235 *vegan* (v2.5-7) (Oksanen et al., 2020) and *cluster* (v2.1.2) (Maechler et al., 2021) and visualised
236 with *ggplot2* (v3.3.5) (Wickham, 2016) and *dendextend* (v1.15.2) (Galili, 2015).
237 We used a consensus approach for validating cluster results – optimising cluster selection
238 and partition by assessing several stability and internal validation metrics (Supplementary Data,
239 Table S6) (Brock et al., 2008) and visualised using non-metric multidimensional scaling (nMDS)
240 plots (Field et al., 1982) using *vegan*. Specifically, we assessed: (1) inter-cluster variation –
241 maximum separation of species between clusters – indicated by higher average distance between
242 species clusters (Rousseeuw, 1987); (2) intra-cluster variance or minimum separation of species
243 within clusters indicated by lower average distance within species clusters (Handl et al., 2005);
244 (3) high silhouette width coefficient value and Dunny Smith residuals (Dunn†, 1974;

Rousseeuw, 1987) representing optimal cluster compactness and separation qualities; and lastly, (4) optimal evenness or balance of cluster composition indicated by the number of species in each cluster (Legendre & Legendre, 1998). Trait values that influence a species' occupancy within a cluster were visualised using heat maps illustrating the importance of trait values to the composition of each cluster.

Trait-based vs taxonomic diet variation

Historical albacore diet composition across geographies were visualised using frequency of occurrence data from 26 studies that yielded 60 observations of diet composition, because the other 3 studies in this dataset and their 9 observations included presence only data. To visualise overall contributions of prey trait guilds to albacore diets, we calculated a normalised index of contribution for each prey species relative to (i) the trait guild they were classified in and (ii) the sum of frequency of occurrence data within each observation per study. Of note, several species with incomplete trait information are therefore 'not classified' with trait guilds and are included in illustrations of diet composition.

For further statistical analysis of trait-based variance in albacore diet composition across geographies, all data from the 26 studies and 69 observations were transformed to presence/absence to meet the model data distribution requirements. Poorly sampled locations were excluded from analyses (samples from South Pacific, South Atlantic and Indian Oceans),

as well as rare species that only occurred once or twice in this reduced dataset. We therefore compare the diet composition for albacore from sampling locations in the North Pacific (samples mainly come from the California Current System), North Atlantic (largely representing North Atlantic Drift), and Mediterranean Sea, providing us with 57 observations of albacore diet composition and including 98 species.

We use a fourth-corner, model-based approach (Dray & Legendre, 2008; Brown et al., 2014), which builds on the generalised linear modelling (GLM) framework (Nelder & Wedderburn, 1972) to simultaneously test how the composition of albacore diets (L matrix of species presence/absence) differed as a function of two different types of explanatory variables: an environmental variable (R matrix, here containing geographic locations sampled) and prey trait information (Q matrices), producing the trait-environment interaction (QxR) or the fourth corner solution to a multi-matrix problem. We therefore built 3 models to test the role of species identity (no traits) or two types of trait information (individual trait values Q1 and seven trait guilds Q2), and geographic location (R) in explaining the presence of prey types (L) across the global data set (Table 2).

We used a binomial distribution for presence/absence data, analysed via logistic regression (with logit link function) using the *traitglm* function in the R package *mvabund* (version 4.1.12) (Wang et al., 2021). We include a species effect in models (i.e., a different intercept term for each species), akin to fitting a random effect variable to account for differences in absolute number of species occurrences (Brown et al., 2014; Wang et al., 2021). Additionally, models were fit with a LASSO penalty, specifying the fitting method as '*glm1path*', using penalised likelihood to impose a constraint on estimates of model parameters (Hastie et al., 2009;

287 Brown et al., 2014). This constraint shrinks coefficients to zero when not statistically significant,
288 providing a combined approach for variable selection, p-value adjustment for multiple models,
289 and parameter estimation to evaluate the magnitude and significance of an explanatory variable
290 (Hastie et al., 2009). Trait-environment relationships for individual trait variables and
291 constructed trait guilds were illustrated as heat maps indicating the interaction strength, and
292 positive or negative correlation between trait information and geographies sampled. Model fit
293 was assessed by plotting multivariate residuals against fitted values and plotting quantile-
294 quantile (Q-Q) plots. Multivariate data were previously screened for broad trends using
295 conditional boxplots (Zuur et al., 2010), for overdispersion and outliers by nMDS plots (Field et
296 al., 1982) using *vegan*. All model assumptions were met.
297
298 **3. Results**
299
300 *3.1 Taxonomic and trait diversity in albacore diets*
301

Our synthesis reveals the large biodiversity of prey consumed by albacore globally (Figure 1). Prey hailed from 7 classes representing 203 families; mainly of ray-finned fishes (n = 108 families of prey), cephalopods (n = 29), and crustaceans (Malacostraca n = 45, Hexanauplia n = 6), and also including pelagic gastropods (n = 6), salps (n = 2), one appendicularian, one branchiopod, one hydrozoan, and one elasmobranch (an unknown Squalidae species) (Supplementary Information, Figure S3). Of these, 308 taxa were reported to species level, with a further 279 taxa identified at variable resolutions from genus to order. Whilst the rate of species accumulation appears to level off in well-sampled locations such as the North Pacific, North Atlantic, and in the Mediterranean Sea (Figure 1b/c), an unknown and likely just as large diversity of prey remains to be studied in the South Pacific, South Atlantic, and Indian Oceans (Figure 1b/c). Additionally, out of 308 prey species, 201 were observed in < 10% of stomach samples within any study (Figure S3). Individual traits varied across phylogeny and recurred across unrelated prey taxa (Figure 2).

3.2 Albacore prey trait guilds

318 We obtained complete trait information for 292 prey species and these were optimally classified
319 into seven trait guilds reflecting different combinations of four traits affecting predator-prey
320 encounter processes (Table 1, Figure 3a). We selected 7 clusters by optimising cluster validation
321 outputs: (1) higher average distance between species clusters (Rousseeuw, 1987); (2) lower
322 average distance within species clusters (Handl et al., 2005); (3) high silhouette width coefficient
323 value and Dunny Smith residuals (Dunn†, 1974; Rousseeuw, 1987); and lastly, (4) optimal
324 evenness or balance of cluster composition indicated by the number of species in each cluster
325 (Legendre & Legendre, 1998) (Supplementary Data, Table S6).

326 The most taxonomically abundant trait guild consisted of diel migrating mesopelagics
327 (trait guild 2), distinct from the non-diel migrating mesopelagics (1) and least taxonomically
328 abundant (Figure 3). The second and third most abundant groups included the oceanic (or
329 'offshore') epipelagics (5) and coastal and shelf epipelagics (3), followed by seasonal,
330 continental shelf taxa (6) and resident continental shelf taxa (7). Finally, the rarest prey guild
331 globally was the coastal and shelf demersal taxa (4). The hierarchical divisive clustering
332 technique for 7 optimal clusters performed well in grouping taxa that are also clustered based on
333 their trait values in multivariate space (Figure 3b; Supplementary Information, Figure S4).

334

335 *3.3 Historical trait-based albacore diet composition*

336

337 Almost all trait guilds were observed in albacore diets in nearly all locations sampled (Figure 4) .
338 The Mediterranean was characterised by a relatively high contribution of samples containing
339 seasonal shelf taxa, with pulses of resident shelf taxa, diel migrating mesopelagics and oceanic
340 epipelagics at different points in time (Figure 4). North Atlantic samples were also characterised
341 by high prevalence of samples containing the seasonal shelf taxa and resident shelf taxa (Figures
342 4 & 5), the latter group mainly prevalent in earlier 1930's samples alongside consistent albeit
343 relatively low prevalence of non-diel migrating mesopelagics at that time. From 1968 however,
344 North Atlantic samples oscillate between higher contributions of the seasonal shelf taxa, coast
345 and shelf epipelagics and oceanic epipelagics. These guilds were also highly prevalent in North
346 Pacific diets, and samples from this basin were also characterised by oscillations between coast
347 and shelf epipelagics and oceanic epipelagics (Figures 4 & 5),. Oceanic epipelagics appeared to
348 dominate South Pacific sampling in most years, with intermittent higher prevalences of seasonal
349 shelf taxa and non-diel migrating mesopelagics. Notably in this region, a relatively high
350 contribution of unclassified species were observed in albacore diets lacking complete trait
351 information. Indian Ocean observations were few in number, and diets varied including two
352 important seasons for resident shelf taxa, one season dominated by coast and shelf epipelagics,
353 and consistent but low prevalences of non-diel migrating mesopelagics.

354 Overall, non-diel migrating mesopelagics were primarily observed in diets prior to 1950's
355 samples from the North Atlantic and with high prevalence in select years in the mid-2010s in the
356 Indian and South Pacific Oceans. The coast and shelf demersals were the rarest group across

357 geographies, and observed mainly in North Pacific samples in the 1940's and North Atlantic
358 samples from 1957. Due to low sample sizes, data from locations in the South Pacific, South
359 Atlantic, and Indian Oceans are illustrated (Figure 4) but were not used in further trait-based
360 models. Taxonomic variation in regional dietary signatures (Supplementary Information, Figure
361 S5) was significantly mediated by trait information and trait guilds, particularly for samples from
362 the North Pacific and the Mediterranean (Figure 5).
363

364 ## 4. Discussion

365

366 *4.1 Synthesis of albacore diet diversity and historical trait relationships*

367

368 We reconstructed historical resource use for albacore tuna (*Thunnus alalunga*) globally,
369 highlighting biodiverse diets in this predator (n = 308 prey identified to species, plus an
370 additional 279 prey taxa identified to genus or higher). We quantitatively synthesised this large
371 prey diversity into 7 functional trait guilds using four sets of traits influencing predator-prey
372 encounter rates: prey habitat association, seasonal and diel vertical migration behaviour.
373 Importantly, this study identifies both taxonomic and trait-based variability in diets of albacore
374 tuna globally, and identifies trait-based dietary signatures in albacore beyond taxonomic
375 variability.

376 Our results indicate that both trait information and constructed functional trait guilds
377 serve as useful and rapid classification tools for tracking large-scale shifts in albacore diets in
378 time and space. Importantly, trait-based frameworks enable functional simplification of diverse
379 prey and functionally redundant food web linkages (Link, 2007), especially involving highly
380 migratory pelagic predators. A traits approach may be of particular use for retaining data on diets
381 containing less common species in analysis such as species distribution models and network-
382 based food web models, as these typically risk being excluded from analyses seeking to
383 investigate predator-prey interactions due to insufficient data or insufficient weighting of these
384 species in models. Rare prey species likely contribute to diet characterization in sharing forms of
385 traits likely to be consumed with more common prey species. Thus, trait values or trait guilds are
386 more tractable analytical currencies for ecologists in the context of changing species distributions
387 and trophic interactions (Green et al., 2022). In applying traits to analysing ecological
388 interactions, it will be important to quantify the extent to which traits recur across unrelated taxa
389 (i.e. phylogenetically conserved or not) (Ives & Helmus, 2011). Trait and phylogenetic
390 information are likely not redundant and ideally should both be accounted for in modelling
391 frameworks (Ovaskainen et al., 2017), as both provide different and useful information in
392 characterising trophic interactions between albacore and their prey.

Traits have proven useful in describing albacore foraging dynamics in prior studies. In the South Pacific, previous studies describe albacore diets as largely consisting of mesopelagic and epipelagic prey, and to a lesser extent include surface migrating bathypelagic and coastal reef-associated taxa (Allain, 2005; Allain et al., 2012; Young et al., 2019). Albacore diets in the Indian Ocean have previously been characterised by a reliance on mixed epipelagic to mesopelagic resident prey stocks (Romanov et al., 2020). Our reanalysis of these data within the global synthesis corroborated and extended these previous descriptive observations.

Trait information was rarely used in an explanatory capacity in the North Pacific, North Atlantic and Mediterranean. Most studies from the North Atlantic and Mediterranean, home to some of the earliest and most detailed investigations of albacore diets (especially from the 1930's; Bouxin & Legendre, 1936; Legendre, 1934, 1940), categorised the diets of albacore as 'specialised' (Consoli et al., 2008), of narrow trophic niche width (Teffer et al., 2015), of short food chain length and low trophic adaptability (Pethybridge et al., 2018) compared to the longer food chain lengths and higher trophic complexity of Pacific tuna diets. Our reanalysis of the same data found that three habitat trait guilds accounted for a large proportion of diet composition observations from the North Atlantic and Mediterranean. Mediterranean samples

409 were especially dominated by two trait guilds overall: the seasonal and resident continental shelf
410 taxa. However, in the North Atlantic dominant prey trait guilds shifted over time, and the
411 detailed taxonomic identification by Bouxin and Legendre in the 1930's revealed particularly
412 trait-diverse diet composition. Trait guilds identified in sampling locations from the North
413 Atlantic and North Pacific were also more diverse than observed elsewhere, and included
414 prevalent consumption of continental shelf, offshore to coastal, mesopelagic and epipelagic trait
415 guilds.

416 We posit that investigating trait-based diet shifts in albacore will be a powerful
417 framework for tracking foraging responses to environmental variability. Our review shows clear
418 differences in trait-based diet composition across years and locations sampled. Investigating the
419 extent to which the consumption of trait guilds relates to environmental drivers and climate states
420 requires access to disaggregated diet data (i.e. prey from each individual predator) sampled
421 consistently over time and space. It may be that individual species productivity alternate and
422 shift across environmental gradients and inter-annual cycles, whilst that of trait guilds may be
423 more stable and offer predictive insights (e.g., the productivity of offshore mesopelagics and
424 coastal to offshore epipelagics in relation to environmental shifts). The extent to which species

taxonomic, phylogenetic and trait information explains variation in diet composition needs to be formally tested.

4.2 Synthesis limitations, knowledge accessibility and gaps to overcome

This review also highlights how variable the sampling of albacore tuna diets has been in space and time, with long gaps between studies ranging from a few years to over fifty years apart depending on ocean basin. Historically, the North Pacific and Atlantic basins were the most studied and taxonomically diverse regions for albacore diet composition, with over 100 species of prey identified in each region, particularly in the productive upwelling system of the Northeast Pacific where most samples were taken in this basin (from 1942 to 2010). In contrast, Pethybridge et al. (2018) found decreased dietary diversity in the productive upwelling regions of the Southeast Pacific (from 2000 to 2015) and for which aggregate diet data for albacore were not available for this meta-analysis. Additionally, sampled locations tended to be aggregated within biogeographic provinces of an ocean basin, such as the California Current System for the North Pacific and North Atlantic Drift for the North Atlantic. In most studies examined in this meta-analysis, samples were concentrated in either frontal, upwelling or offshore gyre zones,

thus likely more indicative of regional-scale rather than basin-scale processes. We note that published or open-access historical data were sparse for the South Pacific, South Atlantic and Indian Oceans, where we expect the taxonomic and trait biodiversity of prey consumed could be just as large as in the North Pacific.

Very large disaggregated datasets are needed to understand resource use in highly migratory pelagic predators at both broad and finer spatial scales. Indeed, several project-based, global-scale databases exist for the trophic ecology and resource use of albacore, yellowfin, bluefin and bigeye tunas (Young et al., 2015; Duffy et al., 2017; Bizzarro et al., 2022). The maintenance, expansion and collaborative accessibility of these datasets will enable the production of powerful and predictive models for tuna resource use under climate change. Critically, Young et al. (2015) note both a lack of long-term monitoring and inadequate sampling in some regions, and to that we add that the availability of such data after collection is also a significant hurdle. Tewksbury et al. (2014) and Young et al. (2015) also highlight the ongoing need for international cooperation and collaboration on data. While disaggregated historical data cannot be expected back to the late 1800's, we highlight the need for open science practices moving forward – publicly available raw diet data on commercially valuable pelagic predators.

458 Access to disaggregated diet data at high taxonomic resolution where information on
459 predator size information and prey size (e.g. lengths and widths) are recorded will enable more
460 accurate pairing of trait information with individual prey items (Zakharova et al., 2019). For each
461 trait in this meta-analysis, we needed to select a single trait value per species, and also estimate
462 the most likely life stage consumed for a large proportion of the data. We believe that traits for
463 prey consumed are representative of the life stage-appropriate habitat use and migratory
464 behaviour traits, but greater accuracy could be achieved and a very lengthy data curation process
465 used to ensure current accuracy in trait data could be significantly shortened with disaggregated
466 data.

467 Further, the need for sound design, maintenance and accessibility of large databases is
468 echoed for species' trait information. Many such efforts are publicly available for some
469 taxonomic groups and classes (Froese & Pauly, 2020; Palomares & Pauly, 2020). However,
470 researchers often expend significant effort and personnel towards further processing data from
471 these databases to fill knowledge gaps (Kim et al., 2018), as well as testing and creating
472 synthetic classifications from species-level data. Knowledge on the underlying distribution of
473 traits across environmental gradients is critical to their use as synthetic predictors in changing

474 ecosystems (McGill et al., 2006). This is a key knowledge gap in marine and freshwater
475 ecosystems (Green et al., 2022).
476
477 ## 5. Conclusions
478
479 Syntheses of historic trophic interactions are crucial for establishing baselines in understudied
480 systems and understanding how they may change. We reveal a comprehensive taxonomic and
481 trait-based portrait of the trophic plasticity of albacore. We generate 7 functional trait-based
482 guilds of prey consumed, applicable beyond this work to classifying prey in albacore and other
483 tunas. We highlight the utility of both functional trait guilds and prey trait information for
484 synthesising variation in predator diets. Trait-based models revealed broad biogeographic
485 signatures in albacore diets and corroborated known ecological differences between sampled
486 geographies, warranting further development of trait-based analyses and investigation to
487 understand how stable or flexible trait-based biogeographic resource use may be for highly
488 migratory pelagic predators, as pelagic ecosystems are altered by climate change and shift to
489 novel states. Ultimately, further modelling applications that use trait database products in
490 predator diet analyses frameworks will shed light on the extent to which future data collection

and modelling efforts in pelagic systems will benefit from a focus on traits (rather than taxonomic identity alone) when seeking to characterise the effect of trophic interactions on predator redistribution.

Acknowledgements

We are grateful to the Lenfest Ocean Program, and Pew Charitable Trust (GRANT 00032174), and MEOPAR (GRANT 0052372) for funding and regular support. Future Seas I and II (NOAA's Coastal and Ocean Climate Application COCA Program (NA17OAR4310268); NOAA's Climate and Fisheries Adaptation CAFA Program (NA20OAR4310507)). We sincerely thank Prof. David Warton in the School of Mathematics and Statistics at UNSW for support in multi-matrix modelling and use of *mvabund* R package. We thank Dr. Miram Gleiber, and all anonymous reviewers, for providing valuable feedback on manuscript drafts. We are especially grateful to innumerable scientists, fishermen, government-based ecosystem monitoring and data collection initiatives for over 100 years of historical data, collected, published or reported, archived, at least in aggregate form, and made available to us through many online requests to numerous libraries across the world. The authors declare no conflict of interest.

Authorship Statement

NH led the design, data collection, analysis and writing. LC, SG and BM contributed to the framework and design of the meta-analysis. NH, SG, CM, IG and ZR co-developed data collection protocols. NH, CM, IG and ZR co-developed methods for data re-analysis and graphics. LC, SG, EH, SB and MJ acquired funding for and supervised this project, providing direct intellectual support and contributions from the conceptualization through to publication of the research. All authors contributed text and substantial revision to the final manuscript.

Data Accessibility

The database for global and historical albacore diet composition from digitised published and grey literature will be made available on Dataverse's Borealis repository. All code for analyses will be made publicly available on Github (https://github.com/CHANGE-Lab/albacore-diet-global). Both the data and code will be made publicly available through a CC BY 4.0 public-use licence upon acceptance of this manuscript for publication. Given the nature of the data and commercial value of the study species we cannot make data publicly available prior to acceptance for publication of this product.

794 **Tables**

795

796 **Table 1.** Trait variables and values that influence the prey encounter phase of the predation process (Green et al., 2019).

Trait	Variable type	Definitions & relationships of traits for predator-prey interactions
Vertical habitat use	Categorical (demersal, epipelagic, mesopelagic)	Represents the water column position that prey resources primarily occupy (note that species can occur elsewhere, but this trait informs us of their main habitat use).
Horizontal habitat use	Categorical (coastal, continental shelf, oceanic)	Represents the typical position from the coastal to offshore waters that prey resources primarily occupy (note that species can occur elsewhere, but this trait informs us of their main habitat use). Coastal = coastal and reef associated; continental shelf = shelf and slope; oceanic = offshore taxa.
Diel migration	Binary (yes/no)	The relationship of this trait with predation is complicated due to an evolutionary arms race whereby prey species, particularly at larval, young-of-year and juvenile life stages, evolved to undertake these diel migrations to avoid predation, however, visual predators in turn evolved to mirror these migrations and intercept prey at crepuscular hours. We include this trait for exploratory analyses and generation of hypotheses on how this may affect predator-prey interactions for albacore tuna.
Seasonal migration	Binary (yes/no)	Represents whether prey species are seasonally abundant in the system, either in the form of seasonal spawning aggregations or seasonal migrations within the system, or local resident prey present at similar abundances year-round.

797

798 **Table 2.** Model design, variables and matrices used in multi-matrix fourth corner analysis.

Diet data (L)	Trait variables (Q)	Environmental variable (R)	Model
Diet composition (SPP)	None	Ocean basin	Diet composition ~ ocean basin
	Q1 – Trait variables (Table 1/S1)		Diet composition ~ traits variables + ocean basin
	Q2 – Trait guilds (Figure 3)		Diet composition ~ trait guilds + ocean basin

Supplemental Information

Appendix A – Literature Search

Table S1. Literature search terms used to identify published papers and historical reports of albacore tuna diets queried from 1900 until 2020 using the Web of Science (Clarivate Analytics, 2020), Aquatic Sciences and Fisheries Abstracts (ASFA, 2020) and Federal Science Library Canada (FSLN, 2020) bibliographic databases. Both the diet research terms and synonymous scientific names for albacore tuna were combined by a Boolean 'AND' clause.

Diet research terms	**Albacore tuna synonymous scientific names**
(diet* OR forag* OR prey) AND	("Thunnus alalunga" OR "Scomber alalunga" OR "Albacora alalonga" OR "Germo alalonga" OR "Germo alalunga" OR "Germo germo" OR "Germo germon" OR "Germo germon steadi" OR "Orcynus alalonga" OR "Orcynus alatunga" OR "Orcynus germo" OR "Orcynus germon" OR "Orcynus pacificus" OR "Scomber alalunga" OR "Scomber alalunga" OR "Scomber alatunga" OR "Scomber albicans" OR "Scomber germo" OR "Scomber germo" OR "Scomber germon" OR "Thunnus alalonga" OR "Thunnus alalunga" OR "Thunnus germo" OR "Thunnus pacificus" OR "Thynnus alalonga" OR "Thynnus alalunga" OR "Thynnus pacificus")

Table S2. Published and historical reports of albacore tuna diet that provided detailed stomach content data. Several older papers, typically prior to the 1980's, needed to be scanned and digitised to PDF format. These are available upon request and all data digitised from published papers and reports are available in our diet database. For every diet report, we recorded the date range, months and seasons of sampling, the median geographic location of albacore tuna collections, the number of albacore tuna collected, fishing gear and time of day for collections.

†These publications were combined as they consisted of three part publication on the taxonomic composition of albacore diets

‡These publications met nearly all criteria for review, but are not included in further analyses as prey were reported at Family, Order and Class levels.

Appendix B – Estimation of albacore prey size/age consumed

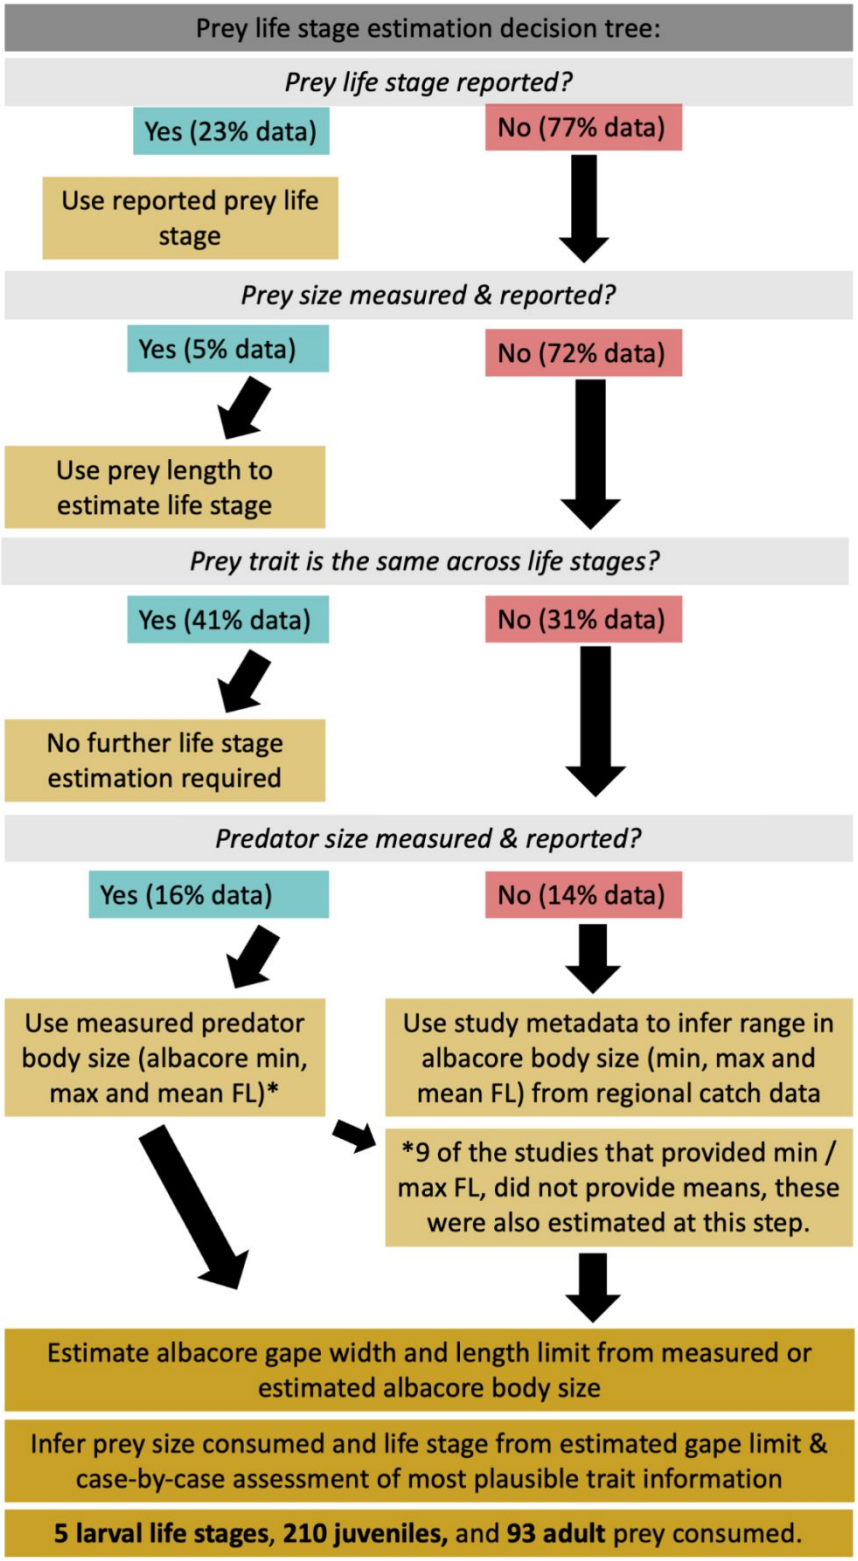
For 94 prey species, we lacked metainformation to assist in their direct life stage estimation and selection of appropriate trait information among different traits for juvenile and adult life stages. We corroborated decisions on selection of appropriate trait information among these species using albacore gape length limits calculated from maximum measured or estimated albacore fork lengths and using the equation developed by (Ménard et al., 2006) for yellowfin tuna to estimate gape limits ranging here from 6.4–11.5 cm across studies and locations sampled. Here we described how data on measured albacore length information were handled and how we estimated fork length information if this was also not measured or reported (Figure S1).

Out of 26 research papers, 16 measured albacore fork length (FL) range, minima and maxima (Figure S2). Of these, seven also reported the mean FL and five an estimated age range or life stage for albacore sampled (e.g., adult, juvenile) (Supplementary Data, Table S3). We also estimated mean FL for the 9 studies that reported FL range but not means (Figure S2), and all FL data for the remaining 10 studies that lacked size or life history information using metadata collected on fishing gear used and matched to gear-specific length data from relevant regional fisheries management organisations.

Of the 10 studies that lacked size or life history information for albacore, four reported the method of sampling (i.e. troll, trawl, longline). For these four studies and to complete the missing mean fork length (FL) for 7 studies noted above, we matched gear-specific length data (range and mean FL) from relevant regional fisheries management organisations (ICCAT, 2020; ISC, 2006) to albacore diet studies by year. We then estimated the likely life stage(s) sampled

using region-specific age and growth curves, and reported sizes at maturity (described in Supplementary Data, Table S3).

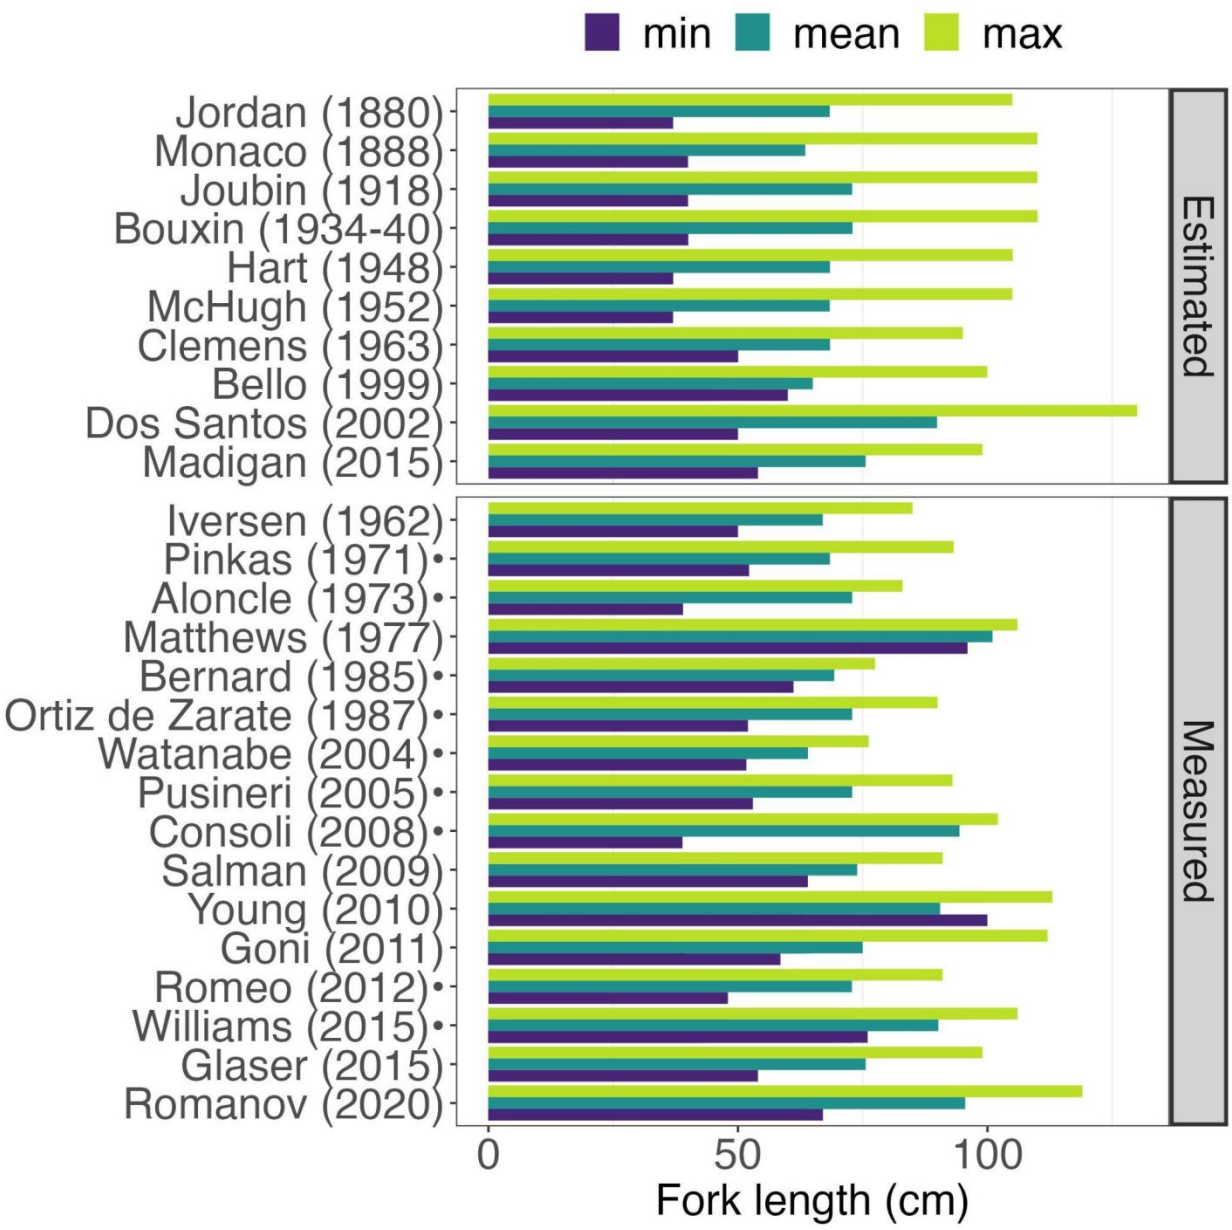
Finally, six historical studies lacked any information about sampled albacore length or age, did not provide catch method and/or were outside any record-keeping time-frames for fisheries catch data. Here, we estimated likely life stage(s) for albacore based on studies that sampled the same geographic area (Supplementary Data, Table S3). We confirmed our life-stage estimations using known albacore ontogenetic and migratory behaviours in the large marine ecosystems sampled (Nikolic et al., 2017). There was no significant difference between the variances of mean, minimum and maximum FL for studies where these parameters were measured or where these parameters were estimated in this study (Figure S2). Overall, we estimate that sampled albacore ranged from 37–119 cm with mean fork lengths of 47–101 cm (Supplementary Information, Figure S2).



52

53 **Figure S1.** Prey species life stage estimation decision tree.

54



55

56 **Figure S2.** Albacore tuna fork length minima (min), mean and maxima (max) obtained from
57 measured and reported data from 16 publications and estimated for a further 10 publications. Of
58 the 16 reporting length information, 9 publications (annotated with •) did not include a mean and
59 this value was estimated in the protocol described in the methods of this manuscript.

Appendix C – Trait-data collection & Analyses

Four trait variables (Table 1) were extracted from a global database of albacore prey traits (Gleiber et al., 2022) for taxa identified to species and for the estimated life stage consumed (Supplementary Data, Table S5). We used online repositories for species-level information, primarily FishBase (Froese & Pauly, 2020), SeaLifeBase (Palomares & Pauly, 2020), and the IUCN Red List of Threatened Species (IUCN, 2020), and by searching descriptive published literature for each species using Web of Science and Google Scholar. Of the 308 species identified in albacore diets, we obtained complete trait information for 292 species for the life stage consumed, for the four habitat use traits used in this meta-analysis: (i) vertical and (ii) horizontal habitat association, (iii) presence of diel vertical migration, and (iv) presence of seasonal migration (Supplementary Data, Table S5).

Vertical and horizontal habitat use traits were directly extracted from online repositories and corroborated alongside species distribution maps, reported depth range and typical depth strata inhabited (Gleiber et al., 2022). Where published literature expanded on or differed from a general value reported by species information repositories, we used the published literature and data. For example, if a species is listed as 'bathypelagic' in FishBase, but we do not have access to the original data and published papers report their distribution as typically 'mesopelagic', we selected their vertical habitat use trait to be 'mesopelagic' for the purposes of this analysis. Trait values for the presence and nature of diel vertical migration or seasonal migration behaviour were collected by keyword searching for each of these terms and for the prey species scientific name on Google Scholar (2020), Web of Science (Clarivate Analytics, 2020), Aquatic Sciences and Fisheries Abstracts (ASFA, 2020) and Federal Science Library Canada (FSLN, 2020)

bibliographic databases. This task was performed and repeated by up to 6 individual data collectors and values were cross-checked between data collectors, multiple published papers and data.

Of note, we further edited vertical habitat use information for two species, *Janicella spinicauda* (Oplophoroidae) and *Lampanyctus crocodilus* (Myctophidae), which were classified primarily as 'bathypelagic' (> 1300 m depth) and appear as such in the database but are also known to occur in the mesopelagic zone listed as secondary habitat in our database. The mesopelagic zone is where these prey were most likely encountered by albacore tuna that are not known to occur in or be able to dive to the bathypelagic at all. Thus for analyses, we relabelled those two species as 'mesopelagic' in order to retain them rather than exclude them from analyses.

Figure S5. Correlation coefficients for the fourth corner solution and significant relationships between taxonomic variability and ocean basins sampled. Here we aggregate 98 species by their phylogenetic order to illustrate the results of taxonomic variability. Coefficients for all trait-environment interactions are presented using a (GLM)-LASSO model (Brown *et al.* 2014). Significant trait-based relationships between albacore diet composition and geography sampled are coloured in relation to their correlation coefficient, and the strength and direction of the relationship.

ape limit (maxGape) for the albacore sampled from the same study as the prey taxa. Appended are the

estimated life stage (life_stage) and associated notes used to select the final life stage assigned to each

species for selection of appropriate trait information. ***See notes below table.

Table S5. Prey species information (class, order, family, species), estimated prey life stages and assoc
